

Building Links and (Local) Networks

Nick DeMarinis

Based partly on lecture notes by Rodrigo Fonseca, David Mazières, Phil Levis, John Jannotti

Administrivia

- Snowcast due Tuesday (9/24) by 11:59pm EDT
- Look for announcement on Gradescope/testing soon
 See our FAQ post for testing resources & common issues!

Next week: we start IP

Tuesday, 9/24

- Start of IP lectures
- Form for selecting your team
- Pre-release IP handout available

Next week: we start IP

Tuesday, 9/24

- Start of IP lectures
- Form for selecting your team
- Pre-release IP handout available

Thursday, 9/26

- Team form due
- IP project official release
- Gearup 5-7pm, CIT 368

Last time: RTT vs. Throughput

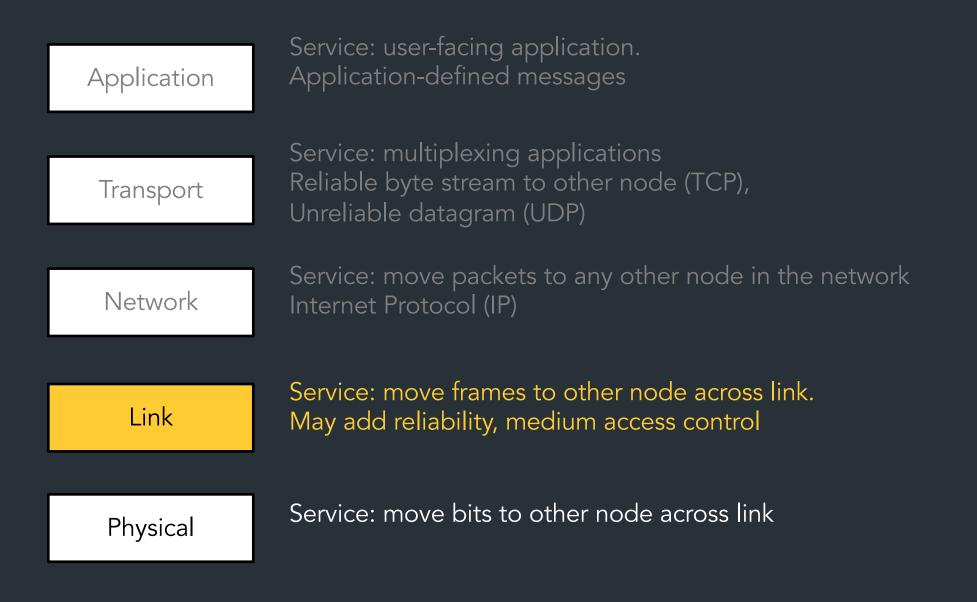

Last time: how to send over a link

Today: how to build *small* network?

- How to share a link
- Case study/fundamental terms: Ethernet (and Wifi)
- How switching works

What does "link layer" mean?

The main idea

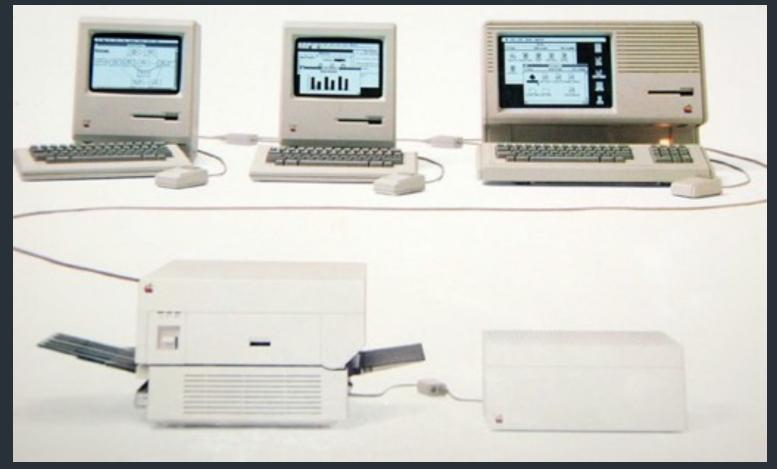

Setting the scene

An AppleTalk network (1980s)

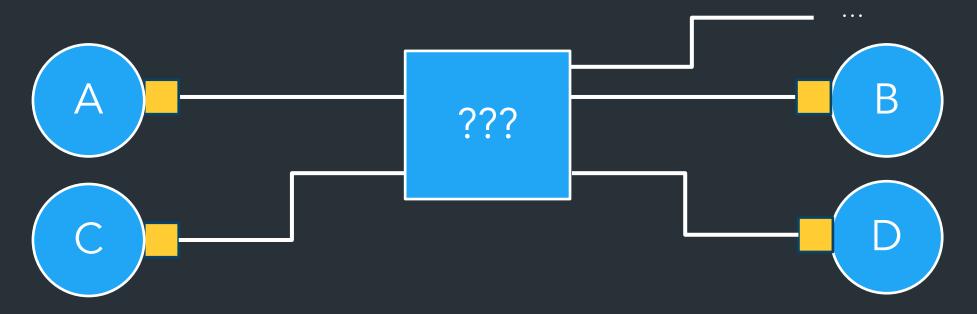

Setting the scene

An AppleTalk network (1980s)

"Small" => Within a building, floor of office, etc Related term: Local Area Network (LAN)

What does "link layer" mean?

- Multiple hosts => shared channel
- Need ways to allow "small" number of hosts to communicate

How to share the channel?

How to share the channel?

Medium Access Control (MAC)

Medium Access Control

Medium Access Control

Idea: No more than one device can be "talking" at one time

Need a protocol for "who can talk when?"

Another example of *multiplexing* => sharing the channel among multiple devices

High-level: MAC approaches

Partitioned Access: divide the channel into fixed slots

- Time Division Multiple Access (TDMA)
- Frequency Division Multiple Access (FDMA)

Problems?

• • •

 \Rightarrow Hard to maximize channel <u>utilization</u> (eg. what happens if only one person is talking?)

High-level: MAC approaches

<u>Random Access</u>: no fixed slots: "ask" to talk, or just talk and hope for the best

- Carrier Sense Multiple Access / Collision Detection (CSMA/CD)
- Carrier Sense Multiple Access / Collision Avoidance (CSMA/CA)
- RTS/CTS (Request to Send/Clear to Send)
- Token-based

Problems?

 \Rightarrow Hard to maintain "fairness"

(eg. one host dominating channel)

Why does this matter?

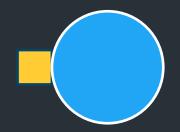

Different types of links solve these problems differently

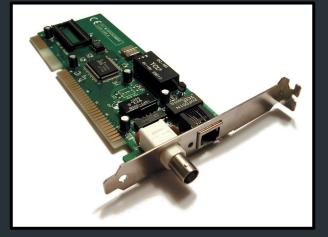

- Ethernet (wired) vs. Wifi (wireless)
- Affects throughput, reliability, etc.

Understand why different links operate differently => How we build the Internet from them

How does a device use a link?

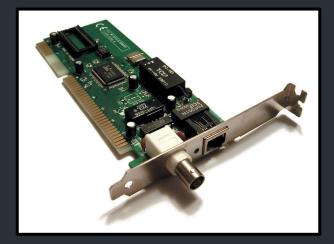

Interface: device that connects something to a network

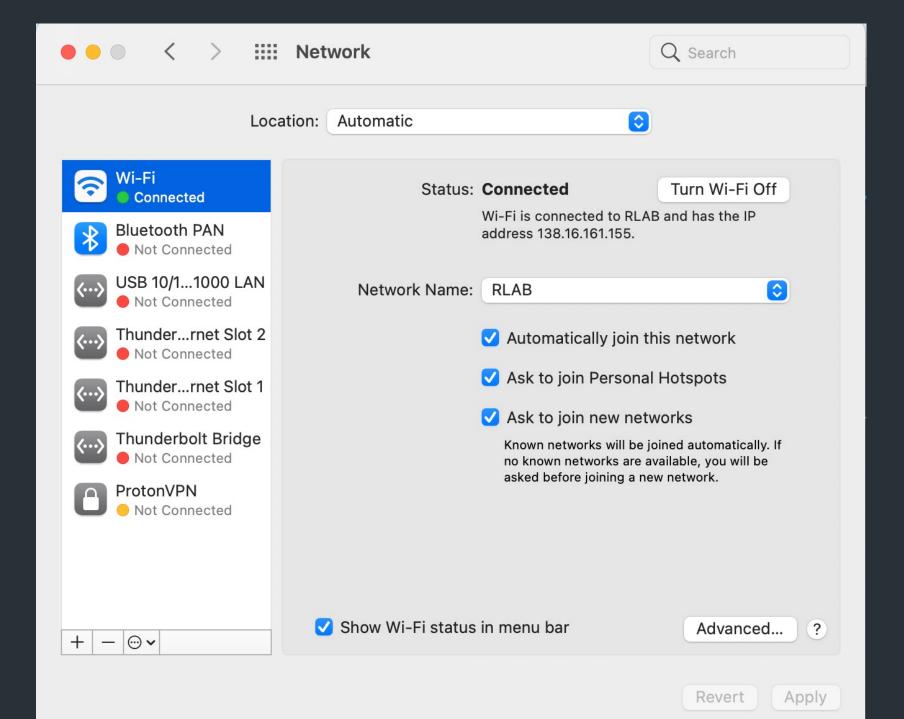

- OS abstraction for a network device
- Physical hardware that does the "talking" => Network Interface Card (NIC)

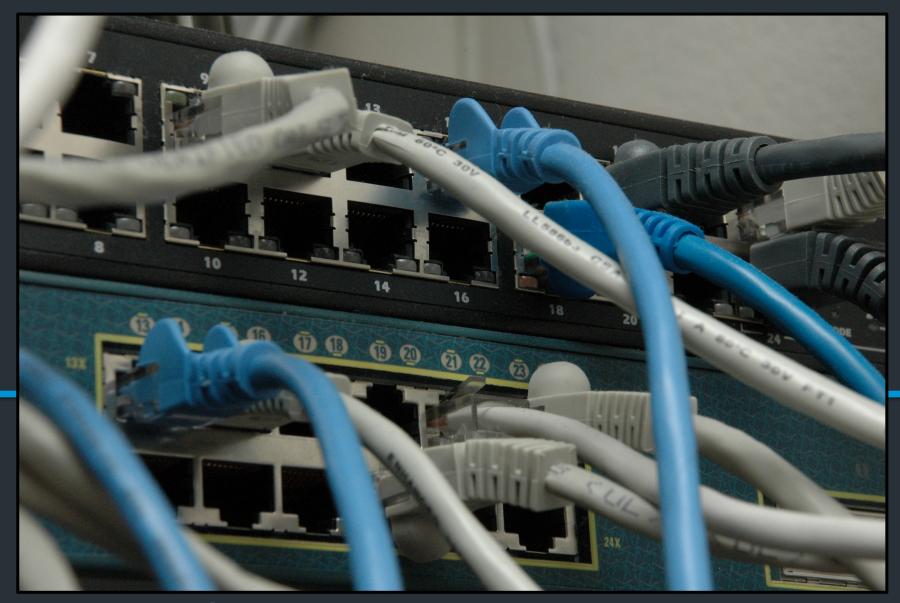

<u>Common interfaces</u>

- Loopback: Virtual, only for local host
- Wifi, Ethernet, Bluetooth, ...

Example: Ethernet

Ethernet

Dominant wired LAN technology, has evolved significantly over time

- Original version (1983): 10Mbps
- Now (commonly): 1Gbps
- Also: 10Gbps, 40Gbps, ...

New developments in physical media, encodings, hardware => higher speeds over time

Ethernet: software viewpoint

Ethernet: software viewpoint

• Logically all hosts are connected to each other

All hosts have an "ethernet address" ("mac address")
 => Globally-unique identifier

• If you know a host's ethernet address, you can send to it

Ethernet: the header

							1			,
Preamble	SFD	Destination MAC Address	Source MAC Address	EtherType	Payload	4	4	,	FCS	
						/	/			

Ethernet: the header

Preamble	SFD	Destination MAC Address	Source MAC Address	EtherType	Payload	4	F 1	FCS	
						1 1			J

- Source address: where packet is from
- Destination address: where packet is going
 ⇒ Devices ask: "Is this my packet?" "Where should I send this
 packet?"

Other stuff

- Preamble: when a packet starts
- FCS: Frame Check sequence (checksum)

Ethernet Addresses (mac addresses)

									-
Preamble	SFD	Destination MAC Address	Source MAC Address	∃therType	Payload	4	7	FCS	
						7 /			

Globally unique, 48-bit address per interface 00:1c:43:00:3d:09 (Samsung adapter)

=> Nowadays, we call them "mac addresses" or "hardware addresses"

Ethernet Addresses (mac addresses)

							1	·
Preamble	SFD	Destination MAC Address	Source MAC Address	EtherType	Payload	4	FCS	
						7 /		

Globally unique, 48-bit address per interface 00:1c:43:00:3d:09 (Samsung adapter)

First 24 bits: <u>Registered to manufacturers</u>

=> Other protocols have adopted this address format (eg. Wifi, Bluetooth, ...)

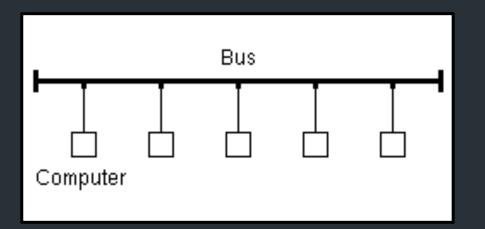

=> Nowadays, we call them "mac addresses" or "hardware addresses"

Ethernet's evolution

Ethernet's evolution

Originally, a shared medium with all hosts

- Basic idea: all hosts can see all frames, read a frame if it matches your hardware address
- Implications?

=>Can have collisons!

Classical Ethernet: Problems

Problem: all hosts in the same "collision domain"

Transmit algorithm

- If line is idle, transmit immediately
- Max message size: 1500 bytes
- If line is busy: wait until idle and transmit immediately

Classical Ethernet: Problems

Problem: all hosts in the same "collision domain"

Transmit algorithm

- If line is idle, transmit immediately
- Max message size: 1500 bytes
- If line is busy: wait until idle and transmit immediately

On Ethernet: generally possible to detect collisions (not always true!)

"Delay and try again later"

<u>Sketch: In Ethernet</u>

- *n*th time: $k \times 51.2\mu$ s, for $k = U\{0..(2^{\min(n,10)}-1)\}$
 - 1st time: 0 or 51.2µs
 - 2nd time: 0, 51.2, 102.4, or 153.6µs
- Give up after several times (usually 16)

"Delay and try again later"

Sketch: In Ethernet

- *n*th time: $k \times 51.2\mu$ s, for $k = U\{0..(2^{\min(n,10)}-1)\}$
 - 1st time: 0 or 51.2µs
 - 2nd time: 0, 51.2, 102.4, or 153.6µs
- Give up after several times (usually 16)

=> Exponential backoff: a useful, general technique

Does this scale?

Ethernet Recap

- Service provided: send frames among stations with specific addresses
- All nodes in the same "collision domain"

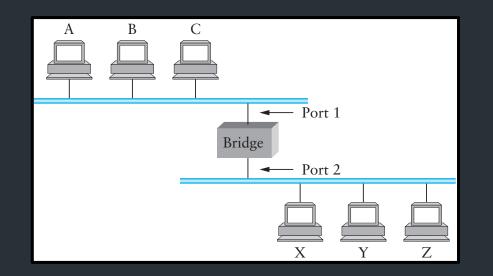

Avoiding collisions

• Early method: bridging

Avoiding collisions

Add some hardware to the network that can separate collision domains

Original way (1990s): bridges

Modern way: switching

Switch: network device that forwards frames (packets) between *ports*

- All hosts connect to a switch
- Collision domain is host-switch
- Switch buffers packets, forwards to destination when its port is idle

How to know which devices is on which port?

MAC learning, how it works

MAC Learning

Switches "learn" which host lives on which port by watching traffic

=>Keeps table of <destination addr => port>

• If you don't know, flood to all ports!

MAC Learning

- Switches "learn" which host lives on which port by watching traffic
- If you don't know, flood to all ports!

MAC learning is just an optimization vs. old version (but a pretty good one...)

MAC table example

	6#sh mac-address-table HWIC: 0 estination Address Address Type VLAN Destination Port				
	5c45.27e0.8383 7641.7b63.584a 5c45.27e0.8381 0000.5e00.0101 ca3f.aee3.e3e6 644b.f012.7f75. f018.9815.8eb8 ecb5.fa13.4677 a0a4.c5c2.4165	Dynamic Dynamic Dynamic Dynamic Dynamic Dynamic Dynamic Dynamic Dynamic	20 10 10 20 20 20 20	GigabitEthernet0/1/3 GigabitEthernet0/1/3 GigabitEthernet0/1/3 GigabitEthernet0/0/1 GigabitEthernet0/1/3 GigabitEthernet0/1/3 GigabitEthernet0/0/2 GigabitEthernet0/0/1	
-	4c71.0c92.4f10 12d3.acae.bbc0 04d4.c448.9cf7	Dynamic Dynamic Dynamic	20	GigabitEthernet0/1/3 GigabitEthernet0/0/1 GigabitEthernet0/1/3	

What can go wrong?

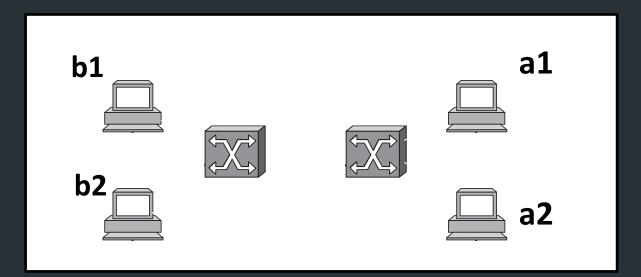

Attack on a Learning Switch

- Eve: wants to sniff all packets sent to Bob
- Same segment: easy (shared medium)
- Different segment on a learning bridge: hard
 Once bridge learns Bob's port, stop broadcasting
- How can Eve force the bridge to keep broadcasting?
 Flood the network with frames with spoofed src addr!

Also: VLANs

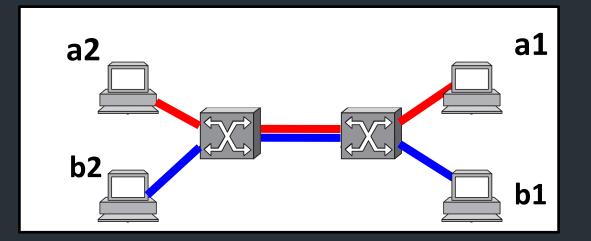

Consider: Company network, A and B departments

- Broadcast traffic does not scale
- May not *want* traffic between the two departments
- What if employees move between offices?

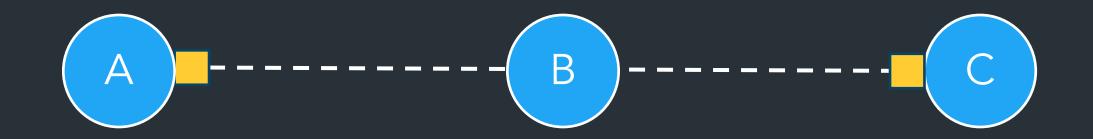

VLANs

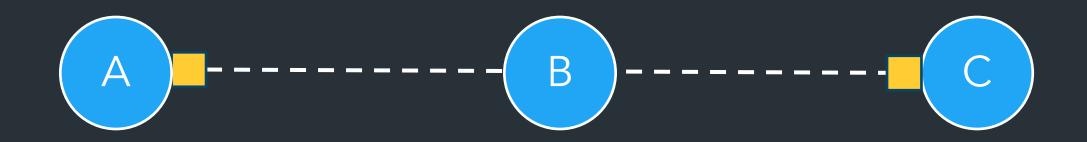

- Solution: Virtual LANs
 - Assign switch ports to a VLAN ID (color)
 - Isolate traffic: only same color
 - Some links may belong to multiple VLANs
- => Easy to change, no need to rewire

How does this all change with wifi?

How does this all change with wifi?

Can't detect collisions anymore!

=> Carrier Sense Multiple Access / Collision Avoidance
=> Try to send: if you don't hear back, assume collision (and maybe retry)

Extra material

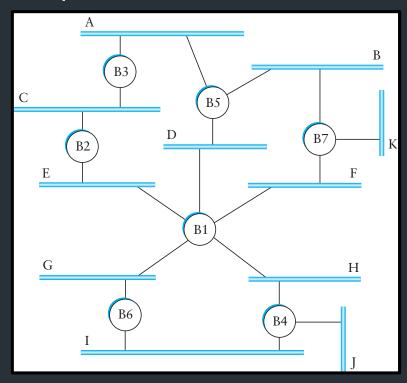

Coming Up

• Connecting multiple networks: IP and the Network Layer

Dealing with Loops

Problem: people may create loops in LAN!

- Accidentally, or to provide redundancy
- Don't want to forward packets indefinitely

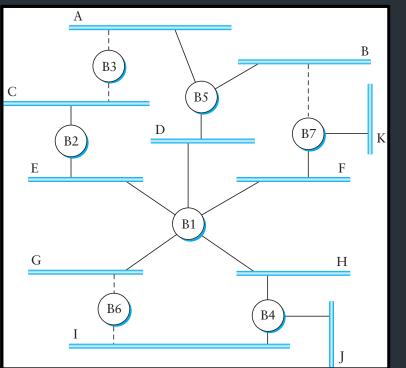

Enter Radia Perlman

"...we have designed an algorithm that allows the extended network to consist of an arbitrary topology. (...) The algorithm (...) computes a subset of the topology that connects all LANs yet is loop-free (a spanning tree)."

Perlman, Radia (1985). "An Algorithm for Distributed Computation of a Spanning Tree in an Extended LAN". *ACM SIGCOMM Computer Communication Review*. **15** (4): 44–53. <u>doi</u>:10.1145/318951.319004

Spanning Tree

- Need to disable ports, so that no loops in network
- Like creating a spanning tree in a graph
 - View switches and networks as nodes, ports as edges

Distributed Spanning Tree Algorithm

- Every bridge has a unique ID (Ethernet address)
- Goal:
 - Bridge with the smallest ID is the root
 - Each segment has one designated bridge, responsible for forwarding its packets towards the root
 - Bridge closest to root is designated bridge
 - If there is a tie, bridge with lowest ID wins

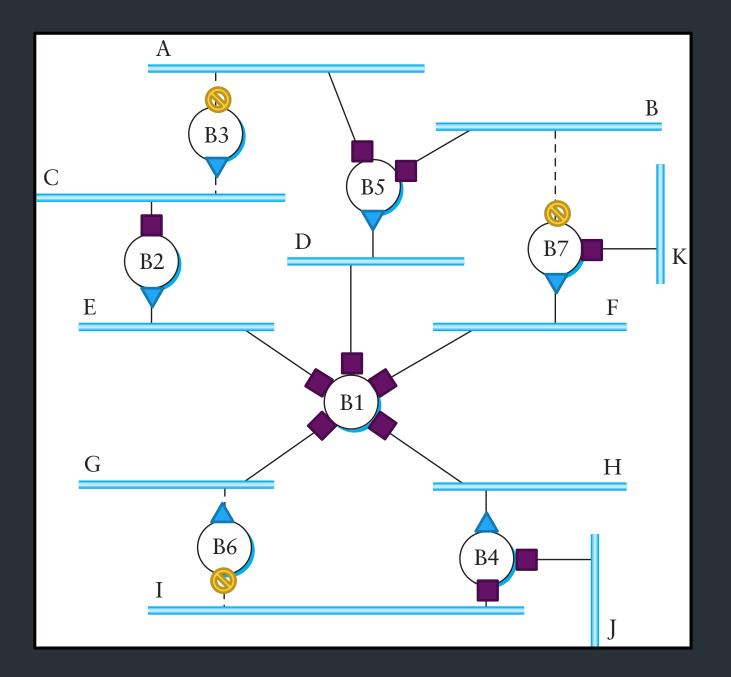

Spanning Tree Protocol

- Send message when you think you are the root
- Otherwise, forward messages from best known root
 - Add one to distance before forwarding
 - Don't forward over discarding ports (see next slide)
- Spanning Tree messages contain:
 - ID of bridge sending the message
 - ID sender believes to be the root
 - Distance (in hops) from sender to root
- Bridges remember best config msg on each port
- In the end, only root is generating messages

Spanning Tree Protocol (cont.)

- Forwarding and Broadcasting
- Port states*:
 - Root port: a port the bridge uses to reach the root
 - Designated port: the lowest-cost port attached to a single segment
 - If a port is not a root port or a designated port, it is a discarding port.

* In a later protocol RSTP, there can be ports configured as backups and alternates.

Algorhyme

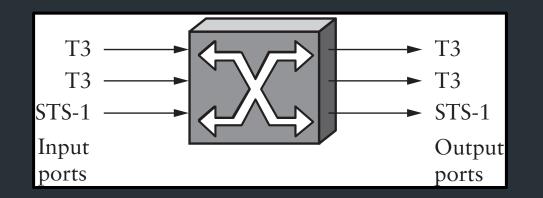

I think that I shall never see a graph more lovely that a tree. A tree whose crucial property is loop-free connectivity. A tree that must be sure to span so packet can reach every LAN. First the root must be selected. By ID, it is elected. Least cost paths from root are traced. In the tree, these paths are placed. A mesh is made by folks like me, then bridges find a spanning tree.

Radia Perlman

Limitations of Bridges

- Scaling
 - Spanning tree algorithm doesn't scale
 - Broadcast does not scale
 - No way to route around congested links, even if path exists
- May violate assumptions
 - Could confuse some applications that assume single segment
 - Much more likely to drop packets
 - Makes latency between nodes non-uniform
 - Beware of transparency

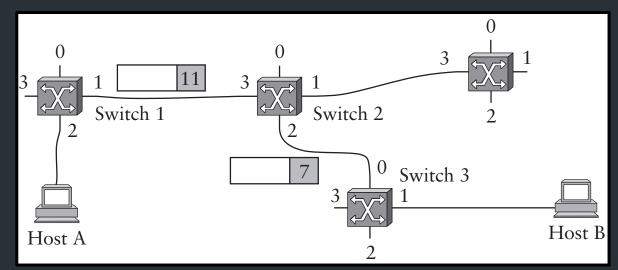

Switching

Switches must be able to, given a packet, determine the outgoing port

- 3 ways to do this:
 - Virtual Circuit Switching
 - Datagram Switching
 - Source Routing

Virtual Circuit Switching

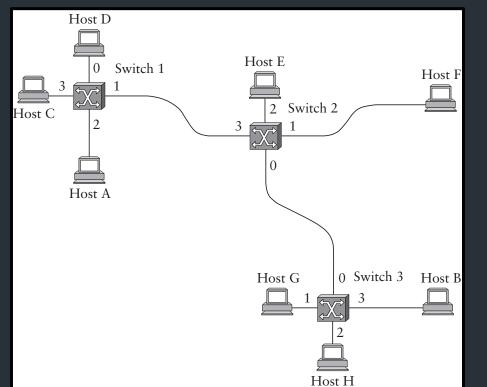

- Explicit set-up and tear down phases
 - Establishes Virtual Circuit Identifier on each link
 - Each switch stores VC table
- Subsequent packets follow same path
 - Switches map [in-port, in-VCI] : [out-port, out-VCI]
- Also called connection-oriented model

Virtual Circuit Model

- Requires one RTT before sending first packet
- Connection request contain full destination address, subsequent packets only small VCI
- Setup phase allows reservation of resources, such as bandwidth or buffer-space
 - Any problems here?
- If a link or switch fails, must re-establish whole circuit
- Example: ATM, MPLS

Datagram Switching

- Each packet carries destination address
- Switches maintain address-based tables
 - Maps [destination address]:[out-port]
- Also called connectionless model

Switch 2

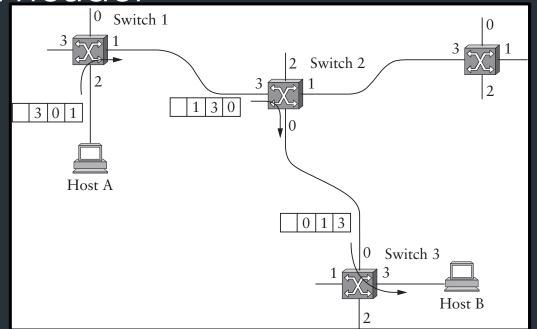

Addr	Port
А	3
В	0
С	3
D	3
E	2
F	1
G	0
Н	0

Datagram Switching

- No delay for connection setup
- Source can't know if network can deliver a packet
- Possible to route around failures
- Higher overhead per-packet
- Potentially larger tables at switches

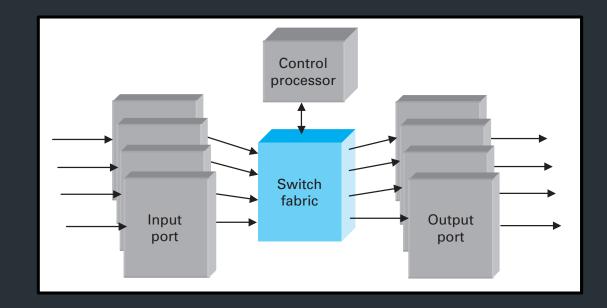

Source Routing

- Packets carry entire route: ports
- Switches need no tables!
 - But end hosts must obtain the path information
- Variable packet header

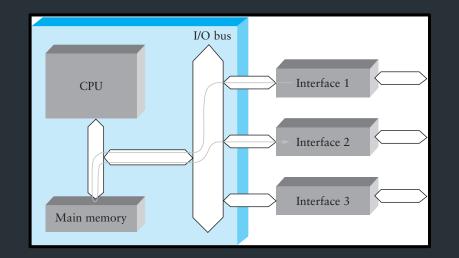

Generic Switch Architecture

- Goal: deliver packets from input to output ports
- Three potential performance concerns:
 - Throughput in bytes/second
 - Throughput in packets/second
 - Latency

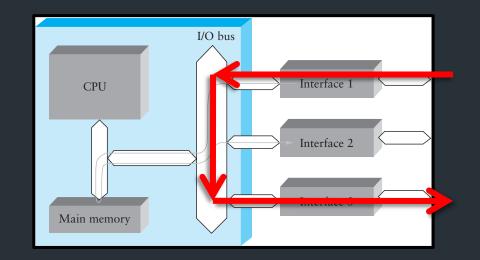

Shared Memory Switch

- 1st Generation like a regular PC
 - NIC DMAs packet to memory over I/O bus
 - CPU examines header, sends to destination NIC
 - I/O bus is serious bottleneck
 - For small packets, CPU may be limited too
 - Typically < 0.5 Gbps

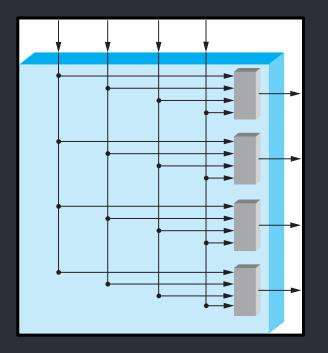

Shared Bus Switch

- 2st Generation
 - NIC has own processor, cache of forwarding table
 - Shared bus, doesn't have to go to main memory
 - Typically limited to bus bandwidth
 - (Cisco 5600 has a 32Gbps bus)

Point to Point Switch

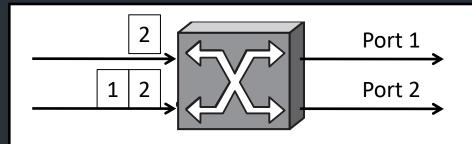

- 3rd Generation: overcomes single-bus bottleneck
- Example: Cross-bar switch
 - Any input-output permutation
 - Multiple inputs to same output requires trickery
 - Cisco 12000 series: 60Gbps

Cut through vs. Store and Forward

- Two approaches to forwarding a packet
 - Receive a full packet, then send to output port
 - Start retransmitting as soon as you know output port, before full packet
- Cut-through routing can greatly decrease latency
- Disadvantage
 - Can waste transmission (classic optimistic approach)
 - CRC may be bad
 - If Ethernet collision, may have to send runt packet on output link

Buffering

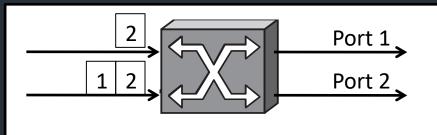

- Buffering of packets can happen at input ports, fabric, and/or output ports
- Queuing discipline is very important
- Consider FIFO + input port buffering
 - Only one packet per output port at any time
 - If multiple packets arrive for port 2, they may block packets to other ports that are free
 - Head-of-line blocking: can limit throughput to ~ 58% under some reasonable conditions*

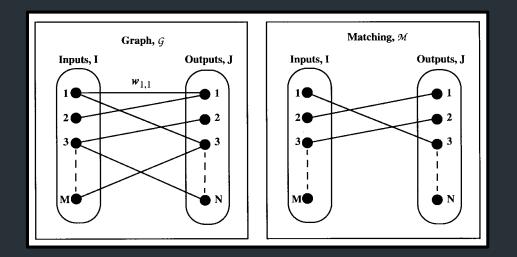

* For independent, uniform traffic, with same-size frames

Head-of-Line Blocking

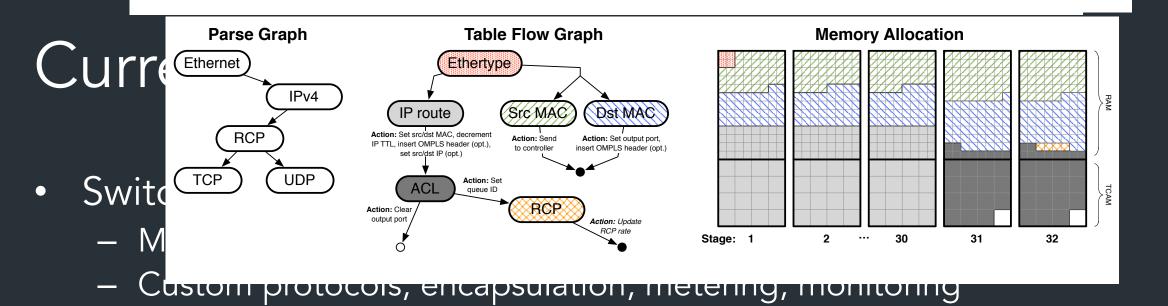

• Solution: Virtual Output Queueing

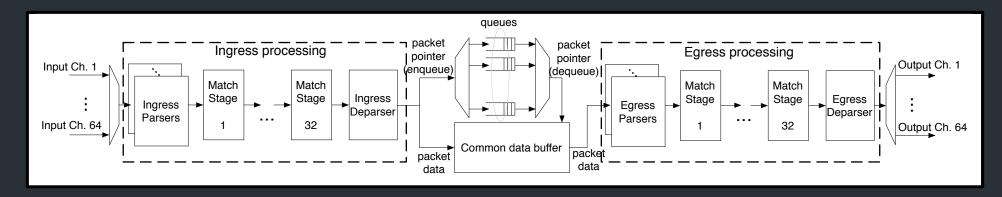

- Each input port has n FIFO queues, one for each output
- Switch using matching in a bipartite graph
- Shown to achieve 100% throughput*

*MCKEOWN et al.: ACHIEVING 100% THROUGHPUT IN AN INPUT-QUEUED SWITCH, 1999

 Current speeds reach 12.8Tbps (32x400Gbps or 256x50Gbps) on a single programmable switching chip
